Plate and screw fixation of arthroscopically assisted tibial tuberosity osteotomy: technique and results

Jarrad M. Stevens[1,2] · Simon B. Barton[3] · Matthew Alexander[1] · Jonathan D. Eldridge[1] · Damian Clark[1]

Abstract

Introduction We describe a fixation technique for tibial tuberosity osteotomies (TTO) utilising a plate and screw construct which adheres to established principles of bone healing. We record and discuss the complication profile and benefits of this technique.

Method The technique is outlined, and thirty consecutive case of TTO fixed with this combination of plate and screws were analysed during a study period from January 2018 to October 2018. All patients were followed up clinically to 3 months post-operation for the purpose of identifying early complications of surgery. Radiographic series were reviewed at 2, 6 and 12 weeks post-operation for evidence of fracture, loss of position, hardware failure and union.

Results All cases went on to clinical and radiographic union by 12 weeks. We identified one case of hardware failure, one case of superficial infection and one case of stiffness requiring manipulation.

Conclusion We have found this technique of plate and screw construct to be effective in arthroscopically assisted TTO fixation leading to consistent union without loss of position with a low complication profile.

Background

Tibial tuberosity osteotomy (TTO) and transfer is a well-described surgical treatment option for a variety of patellofemoral joint (PFJ) disorders. Once osteotomised, the tibial tuberosity can be mobilised in multiple planes addressing patella height and influencing PFJ tracking. Securing the osteotomised tibial tuberosity is a key step in this procedure. Despite wide acceptance and application of this osteotomy, there remains a paucity of literature to guide surgeons on how best to obtain fixation. Ideally, fixation techniques will lend to predictable union, allow functional rehabilitation and carry a low complication profile.

The first described technique of TTO was by Hauser in 1938 and involved a distalisation and medialisation of the patella tendon on a tibial tubercle bone block measuring one-half inch square [1]. This was countersunk and secured into an excised bone block of the same measurements both distal and medial to its origin. This osteotomy was fixed with sutures and reefing of surrounding periosteum. Immobilisation in plaster of Paris was required. Hauser described this operation as a total tendon transplant and so began the lineage of this surgical procedure.

Multiple techniques have now been described for the creation of the osteotomy and its subsequent fixation. Fixation techniques include large-fragment screws, small fragments screws, sutures, staples and cerclage wires. The standard technique for TTO fixation at our institution has utilised two large-fragment, countersunk lag screws. The complication profile of this technique includes but is not limited to: fracture of the tuberosity, fracture of the tibia, loss of position of the tuberosity, non-union and prominent symptomatic metalware [2–7].

In an effort to address these complications, we developed a fixation technique utilising a plate and screw construct which adheres to established principles of fracture

management. The rationale for this technique is explored, and the union rate and complication profile of our first 30 cases are reported.

Method

Using the Avon surgical registry, we identified thirty consecutive cases of TTO fixed with the new technique during a study period from January 2018 to October 2018.

The procedures were performed by specialist orthopaedic knee surgeons (DC and JDE). Patient demographics, indication for surgery, distance of distalisation and/or medialisation is reported. All patients were followed up clinically to 3 months post-operation for the purpose of identifying complications of surgery. Further follow-up was organised on a case-by-case basis.

The patients' radiographic series at 2, 6 and 12 weeks post-operation were reviewed on digital radiographs (Kodak© Picture Archiving and Communication System on a liquid crystal display) for evidence of fracture, loss of position, hardware failure and union. Both anteroposterior (AP) and lateral views of the knee were assessed.

Surgical technique

Preoperative planning includes a comprehensive history and examination which must include alignment and rotational profile screening, supplemented by radiographic investigations. All patients routinely undergo plain imaging including weight-bearing anterior–posterior (AP), lateral and skyline views. To objectively assess patella-femoral morphology, magnetic resonance imaging is performed in all cases. Patella height is quantified using the patellotrochlear index as described by Biedert et al. This informs surgical planning, with the goal of normalising patella height to a patellotrochlear index of 30%.

Setup

All patients are examined under anaesthesia prior to tourniquet application. The patient is positioned supine on the operating table with a foot roll set to hold the leg at 70 degrees and a side support secured low on the lateral thigh to allow for adequate manoeuvering during arthroscopy (Fig. 1). A high thigh tourniquet is placed. A single dose of prophylactic antibiotic is administered at the time of induction.

A diagnostic arthroscopy is performed using a 30-degree camera. An accessory superolateral portal facilitates a diagnostic and dynamic assessment of PFJ morphology, congruence, engagement and tracking. Any intra-articular

pathology that needs addressing is treated at this stage (chondral flaps, synovial plica, etc.).

Anterolateral approach

An anterolateral approach to the tibial tuberosity is performed. A 10-cm curvilinear incision is used: parallel and 3 cm lateral to the tibial crest. It is centred at the level of the tibial tuberosity with the proximal aspect curving laterally towards Gerdy's tubercle (Fig. 2).

The anterolateral incision, through careful skin mobilisation, gives access to both the lateral and medial aspects of the patella tendon and tibial tubercle. Through this incision, the skin can be mobilised to access the proximal medial aspect of the tibia should hamstring harvest be required for adjunct procedures such as medial patellofemoral ligament reconstruction (Fig. 3). It is important to identify the proximal insertion point of the patella tendon, which dictates the proximal extent of the osteotomy and avoids intra-articular extension. The surgeon will need to develop a space behind the insertion of the patella tendon to perform the proximal portion of the osteotomy.

The fascia over tibialis anterior is incised, 1 cm parallel to the tibial crest, leaving a cuff of tissue to repair. The lateral aspect of the tibia adjacent to the proposed osteotomy

Fig. 2 The planned curvilinear incision. The surgeons thumb sits on the tibial tubercle as a point of reference

length can be exposed with the use of a periosteal elevator. The exposure required is dictated by the intended osteotomy length. At our institution, a standard osteotomy measures 70 mm in length. Proximally, the depth is 15 mm from the anterior tuberosity crest and carried distally in a horizontal plane which creates a taper in the distal portion of the osteotomy. We favour a step-cut osteotomy to facilitate biplanar compression during subsequent fixation.
Osteotomy

The knee is placed in extension. A moistened pack protects tibialis anterior as it is retracted to expose the bone for osteotomy, which is marked out with diathermy. Using a fan blade saw, the osteotomy is commenced in the coronal plane from the lateral aspect of the tibia (Fig. 4a). Once this cut

is complete, the periosteum is divided over the osteotomy medially, joining the proximal paratendinous incision. The predetermined length of distalisation is marked out on the osteotomy fragment. It is usually between 7 and 12 mm. Two parallel cuts are made to remove the predetermined length of bone (Fig. 4b). Prior to distalisation, the fragment must be freed proximally, from both bone and soft tissue. A wide osteotome is used to complete the osteotomy from above, starting approximately 2 cm above the proximal insertion point of the patella tendon (Fig. 4c). It is then imperative to release the robust retro-patella tendinous attachments coursing from the tubercle to the fat pad to allow tension-free distalisation. Using a bone holding forceps, the fragment is elevated and the release is performed as demonstrated in Fig. 4d. The tibial tuberosity is now mobile.

Fixation

Distalisation and, if required, medialisation are performed to the desired position. If the described soft tissue releases are performed, the fragment will sit without tension using a bone holding forceps. Temporary fixation with 2-mm K-wires is also possible. Patella–trochlea engagement and tracking can be assessed arthroscopically at this point. A three-hole, 1/3 tubular, small fragment plate is positioned so that the middle hole is centred over transverse, distal osteotomy cut. A 3.5-mm fully threaded bicortical screw is inserted in the distal hole (Fig. 5). A second 3.5-mm screw is placed through the proximal hole of the plate; this is placed in lag mode and will compress the osteotomy. A third screw is now positioned proximal to the plate and is placed as a lag screw.

Assessment and closure

Arthroscopic assessment is once again carried out through the supra-lateral viewing portal, and images are saved at 0, 20, 40 and 60 degrees of flexion. Figure 6 shows views at 20 degrees flexion of the PFJ pre- and post-tibial tuberosity distalisation. Finally, assessment of osteotomy stability is performed by ranging the knee to 90 degrees of flexion, followed by closure. Waterproof dressing, bandages and articulated knee splint are applied. The patient is allowed to weight bear as tolerated with the splint on and range the knee as tolerated at rest.

Results

From January 2018 until October 2018, thirty consecutive cases of tibial tuberosity osteotomy and transfer using the described technique were performed by the authors JDE ($n = 14$) and DC ($n = 16$). Twenty-five patients were female and five were male. The average age of our cohort was 29. The indications for surgery were: patella alta with instability $n = 19$, patella alta with PFJ pain $n = 6$, patella alta with PFJ arthritis $n = 5$. All osteotomies were distalised with the average distance being 9 mm. Five osteotomies were also medialised by an average of 5 mm. A combination of tibial tuberosity transfer and medial patellofemoral ligament reconstruction was performed in 17 cases and a modified Insall soft tissue procedure in five cases.

At the 3-month radiographic check, all cases demonstrated union. We identified one case of hardware failure with the head of a lag screw breaking between weeks six

Fig. 6 Views from the supero-lateral portal at 20 degrees knee flexion. **a** Pre-distalisation, **b** post-distalisation
and twelve. This patient demonstrated both radiographic and clinical union; there was no loss of position, and the broken screw head was asymptomatic.

One patient developed superficial infection and was treated with a 10-day course of oral antibiotics. Under the care of the physiotherapists, this same patient was restricted in movement for an extended period while the infection resolved. This resulted in a stiff knee with range of movement 0°–90°. Our patient underwent a manipulation under anaesthetic at 8 weeks post-index procedure. Post-operative range of movement was 0°–130°, and this range was maintained.

Discussion

Tibial tuberosity osteotomy and transfer, although a straightforward procedure, can result in major complications. Such is the importance of the extensor mechanism; any complication can have a dramatic impact on clinical function. In Fulkerson's original series of 30 tibial tubercle anteromedial transfers, 7% sustained fracture or failure of fixation. Described complications of the procedure included: fracture of the tuberosity, fracture of the tibia, loss of position of the tuberosity, non-union, prominent symptomatic metalware and delayed post-operation functional recovery leading to quadriceps atrophy [2–7]. It is our intention to seek an ideal form of fixation which leads to bone union, avoids symptomatic metalware, maintains position of the osteotomy and allows early functional recovery.

Described techniques for fixation of tibial tuberosity osteotomies include: two large-fragment lag screws [8, 9], three small fragment screws [10] and cerclage wire constructs [11, 12]. These are illustrated in Fig. 7 with our technique for comparison.

Werner et al. compared the cyclical loading profile and load to failure characteristics of tubercle osteotomies fixed with either two 4.5-mm cortical screws or three 3.5-mm screws [13]. They found no clinically relevant difference in the constructs loading characteristics. While both constructs can withstand physiological loading, Johnson et al. reported that 3.5-mm screws were less painful and less likely to need removal than the 4.5-mm screws [14]. The trade-off in screw size is the requirement for an additional screw into the tuberosity.
Davies has comprehensively reviewed the use of 4.5-mm screws vs cerclage wires, staples and sutures in the fixation of tubercle osteotomy in the context of knee arthroplasty [15]. Their work confirmed that screws were superior at resisting cyclical loads at a patella tendon angle of 25°, and this reached significance when testing load to failure.

The described techniques involve internal fixation through the tuberosity into the tibia posterior to the osteotomy, the purpose of which is to provide orthogonal compression and promote union. While this is effective in resisting pull-out, loss of position may still occur due to oblique force vectors generated by the patella tendon. The points of fixation with lag screws are at the tapered screw–neck bone interface and the distal cortex. Translation of the osteotomy and therefore loss of position is possible with an intact construct (Fig. 8).

Surgeons at our institute have begun utilising the construct depicted in Fig. 5 in an attempt to address some of these issues. Our construct utilises screws as they have been shown to be superior to cerclage wires. To avoid prominent hardware, our construct utilises 3.5-mm small-fragment screws. To minimise the number of drill holes in the tuberosity, we use two screws in this fragment. To gain orthogonal compression, the first tuberosity screw is placed in lag mode. To prevent loss of position, the tuberosity is held by a screw and plate fixed distally into the tibia acting as a post to prevent translation and fragment elevation.

This construct has the benefit of being low profile while only utilising two screws into the tuberosity and provides orthogonal osteotomy compression while resisting translation. Future studies are planned to evaluate whether this can

Fig. 7 **a** Two 4.5-mm large-fragment screws, **b** three 3.5-mm small-fragment screws, **c** cerclage wires in various combinations, **d** small-fragment 1/3 tubular plate and 3.5-mm screw construct

be translated into early functional rehabilitation and prevention of quadriceps muscle atrophy.

Conclusion

We have found this technique of plate and screw construct to be effective in arthroscopically assisted TTO fixation leading to consistent union without loss of reduction with a low complication profile.
